1. Background

In recent years, the size, frequency, and severity of wildfires have increased dramatically across the drought-prone Western U.S. Wildfires have been shown to increase basin sedimentation rates by 25 times or more, damaging vital water resources infrastructure. Many previous studies document wildfire disturbance at either the hillslope or continental scales, and thus overlook the interaction of local-scale processes across entire watersheds following a fire. Previous modeling attempts have often been poorly constrained by ground observations and do not accurately quantify alterations to parameters such as soil erodibility, overland flow depth, and mobilization from the post-fire ash layer.

2. Study Domain and Data

- The Cache La Poudre (CLP) Basin is located near Ft. Collins, Colorado.
- This was the site of the High Park Wildfire in June 2012, which burned over 80,000 acres of land and destroyed 259 buildings.
- MODIS LAI data for the burned area from 2000-2017 were analyzed.
- Leaf area reduction based on MODIS LAI data will be compared to observed data obtained in the basin.
- Leaf area reduction on MODIS LAI data for the burned area from 2000-2017 were analyzed.
- Leaf area reduction informed by satellite measurements (Figure 5).
- Pre- and post-wildfire values were compared to obtain a percent reduction in LAI.
- Results show:
  - Immediate post-fire LAI (from data obtained 06/31/2012) = 0.13
  - Immediate post-fire LAI (from data obtained 07/03/2012) = 0.52
- Suggesting a reduction in LAI of approximately 60% due to the wildfire disturbance.

3. Pilot Study – Erosion Algorithm Ensemble

This work builds on a study (Stewart, et al. 2017) performed in the same area that evaluated the performance of sediment models under a physically-based framework.

4. Variable Infiltration Capacity (VIC) Model Overview

The Variable Infiltration Capacity Model is a mesoscale semi-distributed hydrologic model. It operates on a 6km x 6km grid resolution. It is upgraded with an ensemble of 5 hillslope erosion algorithms.

- The Modified Universal Soil Loss Equation (MUSLE) is most sensitive to this change.
- Decreasing LAI affects post-fire sedimentation more strongly than increasing the curve parameter by the same percentage amount.
- The Modified Universal Soil Loss Equation (MUSLE) is most sensitive to this change.

5. Preliminary Sensitivity Analysis

An initial sensitivity analysis was conducted by varying Leaf Area Index (LAI) and the Variable Infiltration Curve parameter, binf (which affects the ratio of runoff in the model) by a set of arbitrary percentages. These results are shown in Figure 4 below.

6. Next Steps

7. Open Questions

- Does modification of LAI and soil disturbance adequately capture wildfire? Are there other processes that can be incorporated?
- For what wildfires or regions do data for post-wildfire sedimentation exist?

Key scientific questions of this study:

- How can wildfire disturbance be simulated and used to predict and prepare for streamflow and erosional effects that occur immediately following an event?
- How much improvement is seen in modeling accuracy by capturing local-scale processes constrained by remotely sensed and in-situ ground observations?
- In a drying West, what effects will future drought events have on the security and availability of water resources?
